Properties of molten CaCO$_3$ at high pressure

J. Hudspeth$^1$, C. Sanloup$^{1,*}$, Y. Kono$^2$

Abstract

We report here the structure of molten CaCO$_3$ studied by in situ X-ray diffraction using a Paris-Edinburgh press up to 8.7 GPa. Variations are observed in the medium range order with shrinkage of the intermolecular contributions, reflecting higher packing efficiency of the carbonate molecules. Density of the melt is obtained from the radial distribution functions, assuming a constant coordination number of 3 for the C-O contribution. Bulk modulus values increase by a factor of 2 over the experimental pressure-temperature range, reaching a value similar to that of underlying crystalline phases at the highest pressure investigated. These are the first direct density measurements of compressed CaCO$_3$ melt; they agree well with recent ab initio predictions (Li et al., 2017), which implies that the reported flattening of the melting curve followed by a slightly negative curve above 8 GPa cannot be due to crystal-melt density inversion. Instead, the enthalpy of fusion is likely responsible, and we note the peculiar high diffusivity of oxygen in crystalline calcite-V in this regard, with further implications for the mobility of carbonate melts at depth.

Introduction

The geological importance of carbonate melts is linked to their ability to trigger melting at depth (Jones et al., 2013). As such, the properties of carbonate melts are key in processes ranging from incipient melting at the oceanic lithosphere-asthenosphere boundary and lubrication of tectonic plates (Gaillard et al., 2008), to pervasive metasomatism of the continental lithospheric roots (Foley, 2008).

Experimental measurements of the physical properties of molten carbonates under high pressures ($P$) are very scarce however. This contrasts with the advances in knowledge on silicate melts under $P$ over the last decade, as reviewed in Kono and Sanloup (2018), and is due to the extreme difficulty in confining such low-viscosity melts for long durations. Structural data at ambient $P$ have been collected on Li$_2$CO$_3$, K$_2$CO$_3$, LiKCO$_3$ melts using neutron diffraction (Kohara et al., 1998), and Na$_2$CO$_3$ using X-ray diffraction (Wilding et al., 2016). The effect of $P$ on melt compaction, i.e. the bulk modulus, has been assessed for alkali carbonate melts by combining ambient $P$ density and acoustic velocity measurements (Liu and Lange, 2003), and from the melting curve for K$_2$CO$_3$ (Liu et al., 2007). In situ high $P$ density measurements are restricted to two $P$ points for molten K$_2$Ca(CO$_3$)$_2$ (2.75 g cm$^{-3}$ at 2.5 GPa, 950 °C, 2.58 g cm$^{-3}$ at 2.5 GPa, 1150 °C) and 2.80 g cm$^{-3}$ at 4 GPa, 1050 °C) using the falling sphere technique (Dobson et al., 1996). These first in situ density measurements were complemented by a study of the viscosity of K$_2$Ca(CO$_3$)$_2$ and K$_2$Mg(CO$_3$)$_2$ melts up to 5.5 GPa (Dobson et al., 1996). Such viscosity measurements were very challenging at the time, i.e. before the advent of high speed cameras required to accurately capture rapidly falling spheres. The ultralow viscosity, i.e. two orders of magnitude lower than for molten basalt at 1900 K, was nonetheless confirmed for calcite and dolomite melts (Kono et al., 2014), with no $P$ effect observed up to 6.2 GPa. This latter study also reported the structure of CaCO$_3$ melts but information was restricted to distances greater than 2 Å, excluding the C-O bond.

In contrast, there are several reported melting curve measurements, as these do not require long experiments and sample integrity can be preserved. Of particular interest is the report of a flattening of the CaCO$_3$ melting curve at 8 GPa followed by a slightly negative slope up to the calcite-aragonite-melt triple point at 13 GPa (Li et al., 2017). This evolution is unique amongst carbonates, with stronger and positive slopes reported for Na$_2$CO$_3$ and MgCO$_3$ (Li et al., 2017). The flattening of the CaCO$_3$ melting curve was attributed to a density crossover between solid and liquid CaCO$_3$. However, such crossover is only predicted theoretically near 17 GPa, and this discrepancy was attributed to approximations in the ab initio calculations, highlighting the need for further experimental measurements of melt density.

We report here structural and density data on molten CaCO$_3$ from in situ X-ray diffraction up to 8.7 GPa and 2073 K, an experimental $P$-$T$ range that corresponds to upper mantle...
conditions. Attempts to collect data on molten Na$_2$CO$_3$, K$_2$CO$_3$, and carbonate mixtures failed, and consequently no results are reported here for these compositions. This might indicate that these compositions have even lower viscosities than pure CaCO$_3$ melt, resulting in escape of the molten carbonates from the graphite capsule.

### Structural Data

*In situ* energy-dispersive X-ray diffraction data were collected under high P-T conditions (Table S-1) using a Paris-Edinburgh press. The structure factor, $S(q)$, was derived from the X-ray diffraction patterns (Supplementary Information, SI). The $g(r)$ radial distribution function, a measure of the probability of finding an atom as a function of the radial distance $r$, was obtained by Fourier Transform of the spline smoothed $S(q)$.

$$g(r) = \frac{1}{2\pi^2n_0} \int_{0}^{\infty} \left( S(q) - 1 \right) \sin(qr) dq$$

where $n_0 = \frac{\rho N_A}{M}$ is the atomic density in atoms per Å$^3$, $N_A$ is Avogadro’s constant, $M = 100.1$ g/mol is the mean atomic molar mass of calcite, and $\rho$ its mass density (see below). The first peak in $g(r)$ is the C-O intramolecular contribution, which is not expected to change significantly over this P-T range. The second peak in $g(r)$ corresponds to the sum of the O-O and Ca-O first neighbour contributions at $\sim$2.3 Å, and the third peak to the sum of the second Ca-O and first Ca-Ca contributions ($\sim$4.0 Å). The most pronounced changes in $g(r)$ (Fig. 1b) with $P$ are at 3 Å, with an increase of intensity related to the intermolecular O-O distance, and the growth of a shoulder around 3.45-3.5 Å related to the Ca-Ca intermolecular contribution. These observations are consistent with the shrinkage of interatomic distance, most pronounced for Ca-Ca (from 4 Å at ambient $P$), and increase in intensity predicted for both contributions by molecular dynamics (MD) calculations (Vuilleumier et al., 2014), as a result of intermolecular packing upon compression. In contrast, intramolecular distances do not change significantly. The intermolecular packing also explains the observed shift of the first sharp diffraction peak in $S(q)$ (Fig. 1a). Concomitantly, MD simulations indicate a gradual increase of the number of carbonate ions around Ca from 6 as in calcite to 9 as in aragonite. It is not possible to estimate the Ca-C coordination number from the present data due to the prominence of the major contributions of neighbouring Ca-O and Ca-Ca. However, correspondence between Vuilleumier et al. (2014) MD simulations and our results supports their conclusions, i.e. the P-evolution of the liquid structure smoothes out the abrupt changes occurring across the underlying crystalline calcite V-aragonite transition.
Figure 2  Density of molten CaCO$_3$ from experiments (circles: this work, squares: Dobson et al., 1996) and theoretical calculations (Genge et al., 1995; Vuilleumier et al., 2014; Li et al., 2017), compared to the seismological PREM model (Dziewonski and Anderson, 1981), crystalline calcite V (Li et al., 2017), molten hydrous and dry rhyolite (Malfait et al., 2014), molten hydrous and dry basalt (Sakamaki et al., 2006).

### Density Evolution

The density of CaCO$_3$ melts (Fig. 2) is calculated from the area below the C-O contribution to the radial distribution function (Eq. 1 and SI). C is coordinated by three O in the studied P-T range, but C becomes tetrahedrally coordinated above 50 GPa in crystalline MgCO$_3$ (Oganov et al., 2008) and above 76 GPa in crystalline CaCO$_3$ (Pickard and Needs, 2015). How this 3-fold to 4-fold transition translates at very high P in the molten state remains to be investigated. The calculated density values are consistent with MD simulations by Genge et al. (1995), although the mismatch with more recent simulations (Vuilleumier et al., 2014) is larger, but seems to be in agreement with ab initio calculations from Li et al. (2017).

This method has been previously benchmarked for molten fayalite using the same experimental set up (Sanloup et al., 2013). Resulting $K_T$ values are provided on Figure 3, along with a correction of the two lowest P points to the 2073 K isotherm. An alternative method to assess $K_T$ (Egelstaff, 1994) is by extrapolating $S(q)$ to $q = 0 \AA^{-1}$ (Fig. S-2 and SI) as $\lim_{q \to 0} S(q) = \frac{nT_kB_{KT}}{K_T}$, where $k_B$ is Boltzmann’s constant.

This method has been previously benchmarked for molten fayalite using the same experimental set up (Sanloup et al., 2013). Resulting $K_T$ values are provided on Figure 3, along with a correction of the two lowest P points to the 2073 K isotherm. An alternative method to assess $K_T$ (Egelstaff, 1994) is by extrapolating $S(q)$ to $q = 0 \AA^{-1}$ (Fig. S-2 and SI) as $\lim_{q \to 0} S(q) = \frac{nT_kB_{KT}}{K_T}$, where $k_B$ is Boltzmann’s constant.

It is difficult to determine the isothermal bulk modulus, $K_T$, by fitting an equation of state to only three data points on the 2073 K isotherm. An alternative method to assess $K_T$ (Egelstaff, 1994) is by extrapolating $S(q)$ to $q = 0 \AA^{-1}$ (Fig. S-2 and SI) as $\lim_{q \to 0} S(q) = \frac{nT_kB_{KT}}{K_T}$, where $k_B$ is Boltzmann’s constant.

This method has been previously benchmarked for molten fayalite using the same experimental set up (Sanloup et al., 2013). Resulting $K_T$ values are provided on Figure 3, along with a correction of the two lowest P points to the 2073 K isotherm. An alternative method to assess $K_T$ (Egelstaff, 1994) is by extrapolating $S(q)$ to $q = 0 \AA^{-1}$ (Fig. S-2 and SI) as $\lim_{q \to 0} S(q) = \frac{nT_kB_{KT}}{K_T}$, where $k_B$ is Boltzmann’s constant.

Our results confirm the liquid density of CaCO$_3$ estimated from ab initio calculations (Li et al., 2017). There is no experimental data on the thermal equation of state of calcite V due to its very limited T-stability field (<200 K) and strong recrystallisation processes at high T (Suito et al., 2001), but the good agreement between experimental and theoretical estimates of liquid density lends support to theoretical calcite V equation of state (Li et al., 2017). Density crossover between solid and liquid phases may hence only occur at 17 GPa as predicted (Li et al., 2017). The reason for the flattening of melting curve around 8 GPa, followed by a slightly negative slope up to the calcite V-aragonite-liquid triple point, may consequently be related to changes in the fusion enthalpy rather than a density crossover. Calcite V has a very peculiar molecular structure, with the oxygen sublattice being molten and the oxygen atoms diffusing along an undulated circular orbit (Ishizawa et al., 2013). Such high diffusion of oxygen in crystalline CaCO$_3$ phases is unique to calcite, and in particular, it does not occur
in aragonite. Although it is not possible to probe this by X-ray diffraction, it is expected that the change of oxygen mobility also occurs in the molten state from calcite-like at low $P$ to aragonite-like at high $P$. It appears this does not affect the viscosity of the melt vs. $P$ (Kono et al., 2014), as the latter is controlled by the diffusivity of the cations. Due to the gradual nature of the structural changes in the molten state, this highly diffusive state will decrease in the melt at lower $P$ than it does in the crystalline state. Enhanced diffusive motion of oxygen in calcite V is consequently expected to cause a large enthalpy decrease upon melting into an aragonite-like melt. Similarly, a strong increase of the melting enthalpy $\Delta H$ (i.e. $\Delta S$) of water has been measured above 15 GPa and up to the ice VII-superionic ice X transition, associated with enhanced diffusion of H atoms in the liquid (Goncharov et al., 2009).

The unique feature of the melting curve of CaCO$_3$ amongst carbonates therefore seems related to the particularity of calcite V. The existence of a $P$ range with negative melting curve related to variation in fusion enthalpy implies that adding heat to the system will freeze it. Corresponding geodynamical settings could be slab-derived melts entrained in upward plumes rising from the transition zone, as proposed for the generation of deep diamonds (Bulanova et al., 2010). Deep carbonate melts cannot indeed derive from melting in the peridotite + CO$_2$ system but from subducted carbonateous sediments or from metamasotised eclogites (Hammouda and Keshav, 2015), keeping in mind that carbonatic melts produced above 15 GPa get Mg-enriched while Ca-rich melts (Ca# = 0.68-0.70) are reported in the 8-14 GPa range (Thomson et al., 2016), coincidental to the negative CaCO$_3$ melting slope. The nature of deep diamond inclusions also points to the presence of Ca-rich protoliths or calcic melts at depths exceeding 300-350 km (Korsakov and Hermann, 2006; Bulanova et al., 2010). Freezing of melts entrained in a plume might then explain the complex, broken and heavily deformed shapes of deep diamonds, indicating formation in a very viscous environment.

Density and structural data are yet to be collected on other carbonate melts, including alkali compositions, in order to assess the properties of all natural compositions. This will require using faster density/structural probes, due to the challenge of confining such inviscid and highly reactive melts under pressure.
