- Sample Description
- Methods
- Figures S-1 to S-4
- Data Tables S-1 to S-4
- Supplementary Information References
Sample Description

The mid-ocean ridge basalts studied here were sampled during the PACANTARCTIC2 cruise (2004-2005) along the Pacific Antarctic Ridge (PAR) between 53°S and 41°S (Fig. S-1). The goal of the PACANTARTIC2 cruise was to sample the ridge furthest away possible from any hotspot, in order to study the composition of the depleted upper mantle. The morphology (median values of the ridge axis bathymetry and ridge cross-section) of the ridge sampled during the PACANTARCTIC2 is consistent with a normal fast spreading ridge (e.g., Briais et al., 2009), which differs from a hotspot-ridge interaction setting. The closest hotspot-ridge interaction from the studied PAR area is the Foundation hotspot ~800 km north, and the 2nd closest is the Louisville hotspot ~1200 km south. The PAR is a fast-spreading context where along axis fluxes are limited, and thus hotspot contributions are negligible over such long distances. The lack of hotspot influence in the samples studied is further supported by geochemical studies (e.g., Moreira et al., 2008; Hamelin et al., 2010, 2011; Labidi et al., 2014; Bezard et al., 2016). Trace element ratios, such as (La/Sm)$_N$ are within the domain of ‘normal MORB’ (Hamelin et al., 2010). Geochemical compositions in Sr-Nd-Pb-Hf of these samples can be found in Hamelin et al. (2011) and plot close to the DMM end member. The range of radiogenic compositions in that study are attributed to the partial melting of a « marble-cake » mantle assemblage, unrelated to plume-ridge interactions. Additionally, helium isotopes of the Pacific-Antarctic Ridge between 41.5 and 52.5° S show a lack of hotspot influence along that section of the ridge (Moreira et al., 2008).

Tungsten concentrations in the PAR MORBs studied here (n = 18) vary from 6.8 ng g$^{-1}$ to 220 ng g$^{-1}$ (Data Table S-1). The W concentrations are strongly coupled to other immobile and incompatible trace elements such as Nb and Th, and W/Th ratios are within the range of fresh MORB (Fig. S-2). This implies that W contained in the MORB samples studied is derived from their mantle sources (e.g., König et al., 2011) and free from secondary W overprinting.
Figure S-1  Map of the Pacific-Antarctic Ridge. Black dots are dredged samples during the PACANTARCTIC2 cruise. Grey lines are overlapping spreading centres (OSC) bordering second order segmentation of the ridge axis.
**Methods**

**Tungsten concentration analysis**

Tungsten concentrations (Data Table S-1) were determined by isotope dilution using a $^{186}$W spike. Approximately 0.1 g of sample powder was dissolved in a mixture of 4 mL 29 M HF and 1 mL 15 M HNO$_3$, 1 mL 15 M HNO$_3$. 

Figure S-2  Tungsten vs. other highly incompatible trace element concentrations and the normalized La/Gd ratio of the Pacific-Atlantic ridge basalts. Tungsten concentrations from this study, other trace element concentrations from Hamelin et al. (2010), Labidi et al. (2014) and Yierpan et al. (2019). Fresh MORB W/Th ranges from König et al. (2011), altered oceanic crust W/Th ranges from Reifenrötter et al. (2021).
followed by repeated dissolutions in 1 mL 6N HCl. Samples were spiked at the onset of digestion to insure sample-spike equilibration. Tungsten was isolated using ion chromatography techniques similar to the ones described in Nagai and Yokoyama (2014). Isotope ratio measurements were carried out on a ThermoScientific Neptune MC-ICPMS of the Isotope Geochemistry and Geochronology Research Centre (IGGRC) of Carleton University (Ottawa, Canada). Measurements were performed on 1.5 ppb W 0.5 M HNO₃ + 0.05 HF solutions. Two standard deviation measurement precisions are largely 2-4 %, propagated 2 standard deviations are estimated better than 10 % in most cases (largely by uncertainty of the spike concentration). Monitoring the measurement accuracy of isotope dilution concentration analysis with the USGS basalt standards BHVO-2 and BCR-2 yielded 193 ± 18 ng g⁻¹ and 436 ± 47 ng g⁻¹, respectively, which are similar within errors of previously reported concentrations (e.g., Jochum et al., 2016; Kurzweil et al., 2018). Total chemistry blanks were 260 pg, representing 1-2 % of the W analysed in samples.

**Tungsten isotope analysis**

High precision W isotope compositions (Data Table S-2) were also obtained at the IGGRC of Carleton University. Sample masses between 3.4 g and 24.5 g were dissolved and W was separated following similar methods described in Touboul and Walker (2012) and Breton and Quitte (2014). Tungsten separation for isotope analysis was performed using a first 20 mL AG50W-X8 resin (200-400 mesh) column to remove matrix elements, and a second 10 mL AG1-X8 resin (200–400 mesh) column to separate W from other high field strength elements (HFSE). Purified W solutions were passed through an additional AG1-X8 resin (200–400 mesh) micro-column (0.3 mL) mainly to remove Ti traces that could reduce the ionization efficiency of W. Tungsten yields were 50-70 %, procedural blanks ranged between 0.4 to 3.0 ng, respectively, for ~ 440 to 530 ng of W separately representing less than 1 % of the total W.

Tungsten isotope ratios were measured on a ThermoScientific Triton TIMS, using the setup and protocols described in Archer et al. (2017) and Rizo et al. (2019). Results were interference-corrected using the oxygen isotope compositional relations from Archer et al. (2017) and mass bias-corrected by internal normalisation to $^{186}$W/$^{184}$W = 0.92767 (Völkening et al., 1991) (normalisation to $^{186}$W/$^{183}$W = 1.985936 was also performed and results shown in Data Table S-2). The $^{182}$W/$^{184}$W and $^{183}$W/$^{184}$W ratios are reported as $\mu$ notations, which are deviations in parts per million (ppm) from the isotope composition of the Alfa Aesar W standard. This standard yielded $^{182}$W/$^{184}$W = 0.864888 ± 0.000003 (2 s.d.; n = 6), and $^{183}$W/$^{184}$W = 0.467149 ± 0.000001 (2 s.d.; n = 7). Two additional measurements of the NIST standard 3163 yielded mean $\mu^{182}$W = 2.4 ± 6.0 (2 s.d.) and $\mu^{183}$W = -1.4 ± 2.9 (2 s.d.). No residual mass-dependent fractionation is observed in the dataset (Fig. S-3). The $\mu^{182}$W errors of means are ± 2$\sigma$ standard deviations (2 s.d.) of the sample populations, or 2$\sigma$ standard errors (2 s.e.) of the individual measurements.
Figure S-3  \( \mu^{183}W \) vs \( \mu^{182}W \) of the MORB samples of this study, as well as of the Alfa Aesar W standard and the W isotope standard reference material 3163 from the National the Institute of Standards and Technology (NIST). Both \( \mu^{183}W \) vs \( \mu^{182}W \) shown are mass bias-corrected using \( \frac{^{186}W}{^{184}W} \).

Neodymium isotope analysis

Fourteen MORB samples have been analysed for high-precision Nd isotopic compositions (Data Table S-3). Chemical separation and purification of Nd were performed at the Advanced Research Complex of University of Ottawa, Canada, following the protocols of Garçon et al. (2018) and Li et al. (2015), and only the main steps are summarized here. The light-REE were separated from the whole-rock matrix using 200-400 mesh AG50W-X8 cation-exchange resin. The dried light-REE fractions were dissolved in HNO\(_3\) with NaBrO\(_3\) to oxidize Ce to its +4 form and remove it from other light-REE\(^+3\) using columns filled with 100-150 \( \mu \)m Eichrom LnSpec resin. The Na and Br added during the Ce-removal procedure were then removed using AG50W-X8 cation-exchange resin. The Nd was finally purified from Sm and any remaining Ce using thin columns filled with 20-50 \( \mu \)m Eichrom LnSpec resin. Total chemistry Nd yields were \( \geq 90 \% \), the total procedural Nd blank was 16 pg.

High-precision Nd isotope abundance ratio measurements were performed on a ThermoScientific Triton TIMS at the Isotope Geochemistry and Geochronology Research Centre of Carleton University (Ottawa, Canada). Samples were loaded onto zone-refined 99.999 \% Re filaments and Nd isotopes were measured on double filaments and using a 2-step dynamic routine that provided static measurements of all Nd abundance isotope ratios and dynamic measurements of the \( ^{142}Nd/^{144}Nd \) ratio. The mass/charge ratios \( ^{140}Nd/^{144}Nd \) were monitored for Ce and Sm mass interference corrections. Each run consisted of 600 to 1200 ratios measured in blocks of 25 cycles, with an integration time of 8.39 seconds per step and a background measurement of 30s between each block. Data were corrected for instrumental mass fractionation using the exponential law to \( ^{146}Nd/^{144}Nd = 0.7219 \). Samples were measured at the same time as the JNdI-1 Nd standard, and in two
analytical sessions (Session 1 and Session 2; Data Table S-3). For Session 1, repeated measurement of the JNdi-1 standard yielded an average $^{142}$Nd/$^{144}$Nd = 1.141835 ± 0.000004 (2 s.d., n = 14), corresponding to a repeatability of 3.8 ppm. For Session 2, the JNdi-1 yielded an average $^{142}$Nd/$^{144}$Nd = 1.141836 ± 0.000004 (2 s.d., n = 6), corresponding to a repeatability of 3.3 ppm. The average $^{143}$Nd/$^{144}$Nd ratio for the JNdi-1 standard for both sessions was 0.512107 ± 0.000003 (2 s.d.), and within error of the value of Tanaka et al. (2000) of 0.512115 ± 0.000007. The $\mu^{142}$Nd errors of means are ± 2σ standards deviations (2 s.d.) of the sample populations or 2σ standard errors (2 s.e.) of the individual measurements.

The $\mu^{142}$Nd obtained for the PAR MORB samples do not correlate with their $\mu^{182}$W (Fig. S-4).

A database for all available $\mu^{142}$Nd for MORB, OIB and mantle peridotites is provided in the Data Table S-4.
